REFORT NO. 460

SPECIES COMPOSITION BY AGE GROUPS AND STABILITY OF
FISH POPULATIONS IN SECTIONS OF THREE MICHIGAN TROUT
STREAMS DURING THE SUMMER OF 1937

David S. Shetter and Albert S. Hazzard

Introduction

Management of trout waters to maintain dependably good angling is being discussed by fisheries biologists and fisheries administrators, but at present such management would be difficult because of the lack of basic data. For example, almost no information is available as to the composition of typical trout stream populations, the variation in such populations in different habitats, the seasonal changes to which they are subject and the effects upon the populations of angling and artificial plantings of hatchery-reared trout. Although a number of studies have been made of the fish food supply and the feeding habits of trout, no one has satisfactorily correlated these investigations so as to demonstrate selectivity or non-selectivity in feeding or the influence of a given number of fish upon the abundance of bottom food organisms.

Contribution from the Institute for Fisheries Research, Michigan
Department of Conservation and the University of Michigan.

Embody (1929) determined the number, species and size of fish in a New York trout stream by temporarily diverting the flow of a short section into an old channel. Greeley (1933) developed the procedure of blocking sections of stream for seining and has sampled a number of New York streams in this way. Further results of this method have been reported by Moore et al (1934) in New York and by Trippensee (1937) in New Hampshire. The latter critically evaluated the method for different bottom types.

Purposes and Methods

This investigation of sample sections of Michigan trout streams was made:

- 1. To determine the number of trout present.
- 2. To learn the proportion of other fishes found in association with trout.
- 3. To find out the changes in numbers and species occurring during the summer.
- 4. To determine age and coefficient of condition of the trout from scale samples, weights and measurements of the fish taken.
- 5. To learn the degree of stability of the various species by marking captured fish and by removing the entire population in one section each month.

The three streams investigated were the South Branch of the Pine River (Alcona County), the Little Manistee River (Lake County), and the North Branch of the Boardman River (Grand Traverse County). Three portions of the South Branch of the Pine and two of the Little Manistee were studied in June, July, August, and September; on the North Branch of the Boardman two sections were sampled on July 1 and 2, whereas three were studied during late July and mid-August. The sections were chosen

at random, but the wildlife technicians who located them were instructed to select a variety of seinable habitats on each stream. The physical data and habitat characteristics of the several stream portions under consideration are presented in Table 1.

The field methods used in the census work have been described by Greeley (1933). These methods were followed except for certain additions and refinements. Chicken-wire was found to be the most suitable material for supporting the blocking seines, as shown in Figure 1. Specially constructed J-shaped iron stakes approximately two feet long were used to hold the lead lines of the blocking seines to the stream bottom. Plane table maps were prepared for each census area (scale 1 inch = 10 feet). Depths and bottom types were plotted on these charts. Areas were determined by use of a planimeter, and lineal distances were calculated with a map measurer. Stream velocities were obtained by determining the time required for a match to move 30 feet (measured distance).

Refore any section was seined, a bottom-food sample was collected with a one square foot sampling net from the dominant bottom type of that particular section so that some measure of availability of food might be obtained late for comparison later with the food found in the stomachs of fish taken from that particular section.

The fish of each species were counted, weighed, scale-sampled, and measured alive in the field. Weights were taken in grams; standard and total lengths were recorded in millimeters. Live weights of the fish were readily obtained through the use of a Chatillon spring balance (500 gram capacity) equipped with an adjustable dial. A small pan of fresh water was placed on the balance to keep the fish alive; the additional weight was automatically corrected with the movable dial.

census

In all but one section of each stream the fish were released alive after the pertinent data had been recorded. Before release they were marked by fin-clipping, different fins being removed each month so that when recaptured it was possible to tell when they had first entered the catch. The total population from one section of each stream was preserved each month for a detailed stomach analysis. These fish were counted, weighed and measured before initial preservation in ten per cent formalin.

The efficiency of the general method of stream census was not tested as extensively as might be desired, but results from one test on the lower census area of the South Branch of the Fine River, considered the most difficult to seine, indicated that with the probable exception of the muddlers, a very small percentage of fish (all species of minor importance) escaped the original count. On August 13, 1937, the lower census section was blocked and was seined in the usual manner (Figure 2) until no fish was caught or only an occasional muddler was taken, at which time seining efforts normally would have been stopped. After a period of four hours, during which the section was left undisturbed with blocking nets in place, seining was resumed. The fish captured in the check seining consisted of: 6 black-nosed dace, 6 common suckers, and 4 muddlers. These fish represented a total weight of 9 grams.

After this additional seining, the entire crew of seven men lined up at the bottom blocking seine and walked slowly upstream, probing all places where fish might be concealed. Only one fish was observed, a black-nosed dace so small that it could escape through the meashes of a fine-meshed common sense minnow seine.

Scientific names are given in Table 2.

During the course of the regular seining, 131 fish (see Table 3) were captured, representing 89.1 per cent of the total number of fish taken in both regular and check seinings. It should be noted that no trout were caught in the second seining, and as none was observed by the careful scrutiny of the crew at the conclusion of the efficiency test, it was assumed that the entire trout population of this particular section had been captured by the regular procedure. If 89.1 per cent efficiency could be obtained on the most difficult section to seine, probably the figures given for other sections closely approach 100 per cent.

Other tests of the efficiency of this particular method of stream census were conducted during the past summer by Trippensee (1937) in New Hampshire trout streams. All of the sections studied by us were similar to those classed by him as "relatively easy to seine." In this class he estimates the efficiency of the method as between 90 per cent and 100 per cent.

No corrections have been made in the calculated populations per acre and per mile as given in this discussion, inasmuch as the test on the Pine suggests that for trout the error in this method is negligible.

Density of Fish Populations

The species of fish, and the crayfish, which were encountered during the population studies are listed in Table 2. Brook, brown and rainbow trout were present in both the South Branch of the Pine River and in the Little Manistee River, but only brook and brown trout were taken in the North Branch of the Boardman River. Common suckers, muddlers, black-nosed daces, and crayfish occurred consistently in all

^{*} No artificial plantings of fish were made during the period of census.

three streams. Creek chubs, sticklebacks, and lampreys were caught in two of the three streams. Johnny darters were taken consistently only in the Little Manistee River. The remaining species (golden shiners, mud minnows, yellow perch, bullheads, and bluegills) were seined in sections of only one stream.

Numerical results of the population studies on the various stream sections will be found in Tables 3 to 10, and consist of the monthly total of the several species of fish found in each section, the calculated number and weight of fish per mile and per acre of stream, based on the actual number and weight of fish determined for each section. The computations of the number of fish and weight per acre provide the best figures for comparing population densities in different sections of the same stream and other streams.

No calculations of populations have been made for entire streams on the basis of the sections sampled as in most instances the censuses were conducted in portions of streams representing particular trout habitats which could be studied by this method. Reliable estimates of the population of entire streams cannot be computed unless the proportion of the various habitats are accurately known for the entire stream. The calculations per mile and per acre are representative only for the particular habitats studied, and even these figures must be considered tentative because of the extreme variation encountered in similar environments in different months (Tables 3 to 10).

To determine what relationship, if any, exists between trout stream habitat and calculated populations of fish per acre, the salient habitat characteristics of the various sections are given in Table 11 together with the average number of fish and calculated average weight of fish per acre. A numerical rating has also been used to facilitate comparison.

On the basis of the available data, the most productive stream, in pounds per acre of fish and number of trout, is the Little Manistee, followed by the South Branch of the Pine. The North Branch of the Boardman was poorest in calculated numbers, pounds of fish and pounds of trout per acre. From the fisherman's standpoint, the Little Manistee River was also the best, since it produced more legal trout per acre than the South Branch of the Fine or the North Franch of the Boardman. One section of the latter showed no legal trout at any time during the investigations.

The most productive sections were those which, according to past standards, had a relatively unproductive bottom type--chiefly sand.

Those sampled areas which were dominantly of gravel were comparatively low in fish production (Table 11). The one characteristic common to the three most productive sections encountered during the course of the study was a greater average depth than was found in the remaining five sections; the average depth of these three sections (lower, South Branch of the Fine; upper and middle, Little Manistee) average between 14 and 13 inches, while the remainder averaged between 9 and 11 inches in depth. The greater depth of the water may very possibly be an important limiting factor in determining the carrying capacity of the a stream, since this was the only favorable habitat characteristic present in two sections of the Little Manistee River, both of which led, in general, in production of trout and other fish.

Stability of Fish Populations

Some measure of the stability or motility of the fish population of the sections investigated may be calculated from the recaptures of fish marked during the course of the work. In the South Branch of

the Pine River and in the North Branch of the Boardman River all fish seined in both upper and lower census sections were fin-clipped and released after all pertinent data had been recorded. This procedure was also followed on the upper section of the Little Manistee River.

A different fin was removed each month (except in the case of the muddlers); thus in succeeding months fish which had been captured previously were readily separated from more recent inhabitants of the census section.

Analysis of recaptures has been made by considering the total number of trout (all species combined to obtain a sufficient number of individuals), suckers, and muddlers, in the stream sections where recaptures were made. The percentage of marked fish which remained from month to month in the section are shown in the horizontal columns of Tables 12 to 17 and are calculated from the number of fish recovered bearing marks of the preceding months. The net percentage loss (which may have been due to migration, capture by fishermen, predation or other causes of death) is calculated by subtracting the total number of marked fish recovered in any month from the number of marked fish released during the previous month, and dividing the result by the number of such fish released in that month.

Tables 12 to 14 indicate that the net percentage loss of the trout population from month to month may be anywhere from 44 to 94 per cent. The suckers and the muddlers suffered a similarly high loss from month to month, varying from 69 to 100 per cent. In the North Branch of the Boardman River and in the Little Manistee River none of the marked minnows or coarse fish were ever recovered in successive months, indicating that a completely new population had

moved in between the dates of sampling. Evidence of migration, probably of a minor nature, may be inferred from the results of the monthly removal of the fish from the middle sections of each of the streams. Tables 4, 6 and 9 conclusively demonstrate that these sections were repopulated within thirty days.

These data, which definitely suggest that populations of stream fish, both trout and associated species, are relatively unstable in specific areas of stream during the summer months, indicate that calculations of stream populations from counts on one or two short sections of stream at only one period during the year are unreliable.

Age Groups Represented in Populations

The trout scales collected during the investigation were cleaned, mounted in glycerin-gelatin and read by the use of a micro-projector. Scale samples were taken from all trout of legal size (7 inches, total length) encountered in the census sections, and from all the smaller trout, except where it was obvious from length measurements that they were in their first summer of life.

The results of the age study are presented in Tables 18, 19, and 20, in which the total number of trout of each species in each age group by months are given for the three streams. The more significant facts are also shown in Figures 3, 4, and 5.

It appears that the trout population in the censused portion of the North Branch of the Boardman is somewhat abnormal in the distribution of the age groups, since the population consisted almost entirely of brook trout of the O group and brown trout of the O group. The distribution of the age groups of the trout population in the South Branch of the Pine River and the Little Manistee River were more normal in that older age groups were represented. The South Branch of the Fine River, however, had no brown trout of the O group, although two adults were taken.

Rainbows decidedly predominated in the trout population in the Little Manistee (see Figure 3). This predominence prevailed despite the fact that almost 50,000 brown trout, and no rainbow trout, were planted in this area in the last 4 years.

Although the rainbows are by far the rost numerous of the trout in the Little Manistee, and make up the major part of the anglers' catch in this stream (Shetter MS.), this species is not as available to the fishermen as the brooks and browns since according to Greeley (1933) a large proportion of the young descend to Lake Michigan before reaching the legal size of 7 inches. Greeley also reports that only 26.2 per cent of the rainbow trout collected on the Little Manistee in August, 1930 were of legal size in their second growing season. If they had migrated to the lake before the next fishing season, very few would have been taken by anglers. Migratory habits of the rainbow in the South Branch of the Fine River have not been determined.

As will be noted by comparison of data in Table 11 with information in Tables 18, 19 and 20, the shallower, shaded sections which had some submerged cover present generally produced the greatest number of 0 group trout.

Figures 3 to 5 indicate that there is little similarity between any of the streams in the proportion of age groups of different species. But the relationship between the total numbers in each age group of all species combined in each stream was more constant throughout the investigation. Just what constitutes a normal distribution of age groups in trout will be known only when we have gathered more data

of a similar type from more trout streams of the state and when we are able to compare these figures with similar censuses in unfished streams.

Summary

- 1. Intensive studies of the fish populations in three sections of the South Branch of the Pine River, two sections of the Little

 Manistee River, and three sections of the North Branch of the Boardman River were carried out monthly from June to September, 1937. The same sections were blocked and seined each month and the fish found there enumerated by species, and were weighed and measured. Scale samples were collected from all trout above the O group.
- 2. The efficiency of the block-and-seining method of stream census was tested in the most difficult section to seine (lower census section on the South Branch of the Pine River). It was found to be 89.1 per cent effective, comparing favorably with results of similar tests conducted in New Hampshire trout streams. As far as could be determined, the method was 100 per cent efficient on the trout population. Only the very small minnows, muddlers and suckers escaped the original seining.
- 3. From the results of the above seinings and from accurate maps of the census sections, monthly estimates were made of the per acre and per mile populations in the censused portions of each stream. No computations for entire streams have been made because the proportion of the habitats censused is not known for any of the streams in question. The estimates for various habitats must be considered as tentative in the light of the extreme variation found in the same section in different months.

- 4. Recaptures of marked fish in subsequent months indicate that neither the trout nor the "coarse fish" tend to remain in the census areas. Calculations of stream populations on the basis of one or two counts in limited sections at any one time will therefore be inaccurate.
- 5. A study of the age of the trout collected in the census sections of the North Branch of the Boardman indicates an abnormal number of trout of the 0 group. In the South Branch of the Pine and in the Little Manistee the older age groups are present. The oldest trout represented by a few individuals were in the fourth year of life.

Acknowledgments

The authors wish to thank the U. ... Forest Service and the Michigan Civilian Conservation Corps for their continued interest and cooperation throughout the investigations. Man-power for installing blocking nets and seining and transportation was furnished by these agencies. On the Huron National Forest the work was aided by Don Gray, Wildlife Technician, and on the Manistee Purchase Unit by Wildlife Technicians Eugene Kuhne and William Hopkins. Lee Mauer, Supervisor of the Fife Lake CCC Camp, cooperated in the work on the North Branch of the Boardman River.

Thanks are due to Mr. Edwin Cooper of the University of Michigan for his able assistance in the field, and to Mrs. Dorothy Woodbury for her skill and patience in preparing and mounting the trout scales used in age determinations. We are indebted to Dr. F. S. Welch of the Zoology Department of the University of Michigan for the loan of equipment used in areal determinations.

To Dr. Ralph Hile of the U. S. Bureau of Fisheries, and Dr. Carl L. Hubbs, Curator of Fishes at the Museum of Zoology, University of Michigan, we wish to express our thanks for advice and aid in the preparation of certain data.

One brown trout in each category escaped, but included in calculations of population.

² Calculated poundage for 28 brown trout weighed. Does not include possible poundage of escaped fish.

TABLE 11

RELATION OF CERTAIN ENVIRONMENTAL CHARACTERISTICS

AND CALCULATED AVERAGE NUMBERS AND POUNDS OF FISH PER ACRE.

Order of data determined from Tables 1 to 10 inclusive.

Stream and Section		Average depth (inches)	Sh ade	Submerged cover	No. pounds of all fish	No. pounds of trout	Per cent of trout	No. of trout	No. legal trout	Dominant bottom
South	Upper	9.8 (7)	Partly	Excellent	22 (4)	11 (5)	43.0 (2)	597 (2)	13 (7)	Gravel
Branch of	Fidd le	10.9 (5)	Densely	Excellent	19 (5)	12.5 (4)	42.5 (3)	776 (2)	20 (4)	Clay
Pine	L o wer	13.7 (3)	Partly	Excellent	178 (1)	40 (1)	13.6 (6)	448 (5)	100 (2)	Muck and detritus
Little	Upper	17.2 (2)	Partly	Average	55 (2)	35 (2)	24.5 (5)	466 (4)	115 (1)	Sand
Manistee	Middle	17.4 (1)	Exposed	Poor	33 (3)	30 (3)	60.0 (1)	2036 (1)	29 (3)	Sand
North	Upper	10.1 (6)	Partly	Excellent	11 (6)	8 (6)	27.3 (4)	30 (8)	15 (5)	Gravel
Branch of	Middle	11.4 (4)	Exposed	Poor	5 (7)	1.6 (8)	9.0 (8)	101 (6)	0 (8)	Sand
Boardman	Lower	9.1 (8)	Partly	Poor	4 (8)	1.4 (7)	11.5 (7)	60 (7)	8 (7)	Sand

Fifty per cent or more.

TABLE 12

PERCENTAGE OF TROUT POPULATION REMAINING IN LOWER CENSUS SECTION, SOUTH BRANCH OF THE PINE RIVER, FROM MONTH TO MONTH.

Month Marked	Total number of trout in section in month	Number of unmarked trout in section	re	covered in mo	
		in month	July	August	September
June	172	172	53 .0 9	18.14	13.63
July	24	15	•••	20.03	13.32
Augu st	18	11	•••	•••	27 .3 3
Septemb er	33	25	•••	•••	•••
Net percenta	ge loss of marked trout		47.0g	70.84	55 .6 8

Represents number actually released with fins clipped. Five others escaped.

TABLE 13

PERCENTAGE OF TROUT POPULATION REMAINING

IN UPPER CENSUS SECTION, SOUTH BRANCH OF THE PINE RIVER,

FROM MONTH TO MONTH.

Month Marked	Total number of trout in section in month	Number of unmarked trout in section	Percentage of trout marked for month recovered in month				
`ME - 77'da - 4 - Jane 1971, 4 - 4 - 4 - 4 - 4 - 4 - 4 - 4 - 4 - 4		in month	July	Augu st	Septembe r		
June	12	12	8.33	16.72	0.0		
July	31	30	•••	0.96	3.34		
August	41	39	•••	•••	28.211		
September	50	38	•••	•••	•••		
Net percentage	loss of marked trout	91.77	93.62	70.7/12			

TABLE 14

PERCENTAGE OF TROUT POPULATION PENAINING IN UPPER CENSUS SECTION, LITTLE MANISTEE RIVER,

FROM MONTH TO MONTH.

Month Marked	Total number of trout in section in month	Number of unmarked trout in section	Percentage of trout marked in month recovered in month				
		in month	July	August	September		
June	33	3 3	33.011	18.16	6.12		
July	47	36	•••	22.28	16.76		
August	18	121	•••	•••	50.02		
September	15	5	•••	• • •	•••		
Net percentag	ge loss of marked trout	67.0/1	70.2	44.410			

⁸ of these died, leaving 4 to be added to the total number of marked fish recovered.

TABLE 15

PERCENTAGE OF SUCKER POPULATION REMAINING IN LOWER CENSUS SECTION, SOUTH BRANCH OF THE PINE RIVER, FROM MONTH TO MONTH.

Month Ma rked	Total number of fish in section in month	Number of unmarked fish in section	Percentage of fish marked in month recovered in month				
			July	August	September		
June	5 1	5 1	21.5	17.69	1.91		
July	44	33	•••	15.16	o		
August	56	44	•••	•••	o		
Septembe r	86	85	•••	•••	•••		
Net percent	age loss of marked fish	78.511	68.114	98.2			

TABLE 16

PERCENTAGE OF MUDDLER POPULATION RUMAINING IN LOWER CENSUS SECTION, SOUTH BRANCH OF THE PINE RIVER, FROM MONTH TO MONTH.

Month Mar ked	Total number of fish in section in month	Total number of unmarked fish in section in month	Percentage of fish marked in month recovered in month				
			July	August	Septemb er		
June	111	111	13.6/15	11.817	•••		
July	48	33	•••		•••		
August	53	36	•••	•••	•••		
September	84	84	•••	•••	•••		
Net percentag	e loss of marked fish	86.415	88.217	100			

Calculated on the basis of the total number marked up to this month, since muddlers from months after July could not be recognized as they did not have enough fins suitable for clipping.

TABLE 17

PERCENTAGE OF MUDDLER POPULATION REMAINING IN UPPER CENSUS SECTION, SOUTH BRANCH OF THE PINE RIVER, FROM MONTH TO MONTH.

Month mark ed	Total number of fish in section in month	Total number of unmarked fish in section in month	Percentage of fish marked in month recovered in month				
		·	July	Augu st	September		
June	43	43	6 ₃	7.8			
July	11	8	•••	4	7.55		
August	20	16	•••	•••	1.75		
September	46	41	•••	•••	•••		
Net percentag	ge loss of marked fish	93	92.2	92 .5			

Calculated on the basis of the total number of fish marked up to each month since muddlers after the month of July could not be recognized as there were not enough fins suitable for clipping.

TABLE 18

TOTAL NUMBER OF TROUT BY SPECIES IN EACH AGE GROUP

BY MONTHS IN CENSUS SECTIONS OF THE NORTH BRANCH OF THE BOARDMAN RIVER.

Inferior figures under "Number" indicate number of legal fish.

		Number and average total length (mm.) in age groups

All 0-group fish were measured on March 22, 1938 and corrected for shrinkage by a factor of 1.054, as previously determined by Shetter (1936).

One legal brown trout, age not determinable, included in total of legal fish.

Two legal brown trout, age not determinable, included in total of legal fish.

Fig. 1. CCC crew cleaning lower blocking seine during removal of fish from section of South Branch of Pine River.

Fig. 2. Seining the lower section of the South Branch of the

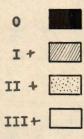

Pine. The upper blocking seine is upstream, just around
the bend. Note the amount of shade and depth of water
in this especially productive section.

FIG. 3. TOTAL NUMBER OF TROUT BY SPECIES IN EACH AGE GROUP BY MONTHS

IN CENSUS SECTIONS OF THE NORTH BRANCH OF THE BOARDMAN RIVER.

AVERAGE SIZE (TOTAL LENGTH IN INCHES) OF AGE GROUP SHOWN AT

RIGHT OF BAR.

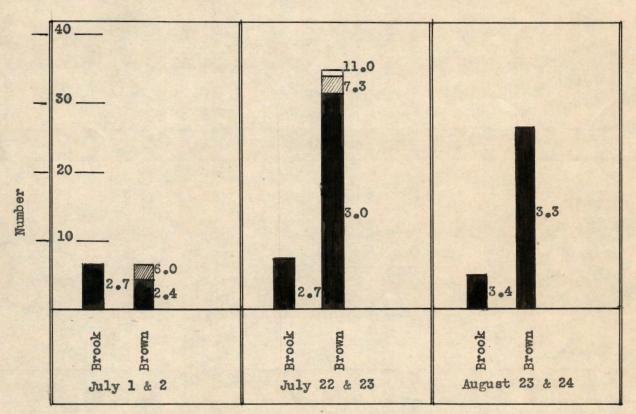

FIG. 4. TOTAL NUMBER OF TROUT BY SPECIES IN EACH AGE GROUP BY MONTHS

IN CENSUS SECTIONS OF THE SOUTH BRANCH OF THE PINE RIVER.

AVERAGE SIZE (TOTAL LENGTH IN INCHES) OF AGE GROUP SHOWN AT

RIGHT OF BAR.

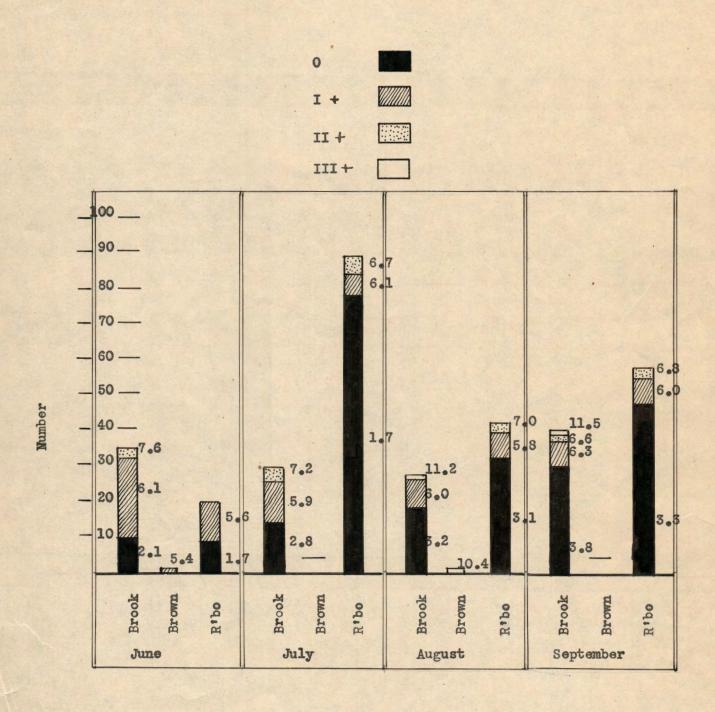

FIG. 5. TOTAL NUMBER OF TROUT BY SPECIES IN EACH AGE GROUP BY MONTHS

IN CENSUS SECTIONS OF THE LITTLE MANISTEE RIVER.

AVERAGE SIZE (TOTAL LENGTH IN INCHES) OF AGE GROUP SHOWN AT RIGHT OF BAR.
